PATENT

MAGNETIC WRITE HEAD WITH PRECONDITIONING GAP

Background and Summary

At present, most digital magnetic recording systems, such as those used for hard disk drives for personal computers, do not erase previously recorded data before recording new data. This is commonly known as recording in a direct overwrite mode. However, it has been found that writing in a direct overwrite mode increases the uncertainty of the exact location where a magnetic transition has been placed corresponding to the new data. This uncertainty reduces the system's signal-to-noise ratio (SNR) which has the practical limitation of reducing the system's effective storage capacity. As the bit lengths in digital recording become shorter from their already submicrometer dimensions, the ability of existing systems to write sharp transitions at particular locations lessens due to the previously written data encountered in the direct overwrite mode. As a result, signal degradation in the form of signal amplitude reduction, output pulse shape broadening, and pulse position shifts are experienced. This continuing progress in reducing the size of bit lengths and track

2

dimensions require even more accurate recording of sharp transitions to achieve digital data density resulting in improved performance. Therefore, erasing previously recorded magnetic information would be desirable in any digital magnetic recording system, but practical implementation of this erase operation remains elusive for many applications. For example, consider the tracks in rigid disk systems. These tracks are narrow, nearing the micrometer width, are separated by distances smaller than even the track width's micrometer dimension, and these track dimensions are rapidly shrinking with each new product iteration seeking greater data density. In these applications, erasing previously recorded data before writing with conventional magnetic recording heads might be thought of in a couple of ways. One such way is for the read/write head to erase the portion (sector) of the track to be recorded on one pass of the head, and then the next pass of the head would be used to record new digital data on the previously erased sector. An obvious drawback with this approach is that it would require a time consuming extra revolution for all write steps. This delay, presently 16 milliseconds for a 3600 rpm disk drive, is larger than any other single delay for the system and would degrade overall data transfer performance. Another approach could include providing a separate erase head physically positioned "upstream" of the conventional write head, and displaced in position as with other prior art video or audio erase heads. In analog audio or video tape recording, an erase step is used to precondition the medium by erasing the old information with a separate erase head. In these systems, the erase head is physically distinct and separated from the recording head spatially and in design. The erase head may be displaced from the record head by several centimeters; may erase multiple tracks of old information in the same pass; may have a large

08822778-032197  
magnetic gap for deep penetration of the magnetic field into the medium; and may use a single DC or AC applied current to erase the medium. However, there are problems in utilizing this approach with digital magnetic recording systems including the problem of physically aligning the two heads with respect to each other and with respect to the track to be overwritten. At present data densities and track dimensions, this is at least difficult and perhaps overwhelmingly challenging with track pitches projected to be 100 nanometers or less, especially considering that the heads must be consistently aligned over time, with temperature and other mechanical deviations providing further complications. Still another approach would include fabricating a second head to perform the erase function directly over the conventional write head. This approach could be considered in thin film heads which are widely used for digital magnetic recording systems. However, there would be significant cost and complexity added to the manufacturing process due to the additional steps involved with this approach.

To solve these and other problems in the prior art, the inventor has succeeded in developing a design for a thin film head with an integrated preconditioning gap which may be constructed with only a slight modification to the present manufacturing techniques utilized to construct thin film recording heads. It is anticipated that this modified construction may be achieved with only a small processing cost and without significantly reducing the expected yield of the delicate thin film manufacturing process. In essence, the inventors' design utilizes the same layering of a first magnetic pole piece, a pancake magnetic coil, and a second magnetic pole piece magnetically coupled to the first pole piece with one set of edges being spaced to form the magnetic gap therebetween. However, the bottom

4

or first pole piece would have an extended length so as to underlie the entirety of the pancake coil, and a third pole piece is provided which magnetically couples to the extended tail of the bottom or first pole piece to thereby encircle the back half windings of the pancake coil. The second gap or preconditioning gap is thereby formed between this additional third pole piece and the second pole piece.

In sum, using conventional thin film manufacturing techniques and present designs, a thin film magnetic recording head may be conveniently manufactured with an intricately formed preconditioning gap to provide an on-the-fly erase function. This device has applicability to both perpendicular and longitudinal recording. Due to its being manufactured in an integral, single head, the preconditioning gap is always aligned <sup>with the write gap</sup> and suffers the same environmentally induced degradation such as through temperature, stress, or the like such that it remains so. Furthermore, there is no intervening spacing between the preconditioning gap and the write head as the center pole piece forms part of the magnetic circuit for each of these two gaps. Therefore, once manufactured, the preconditioning gap is aligned, its performance may be measured and tested to verify its operating parameters, and could be expected to remain in that condition over time and through its useful life. As the center pole piece is energized by a single coil, and the center pole piece forms part of the magnetic circuit for both gaps, there is no requirement for a second magnetic coil. This reduces cost, manufacturing complexity, eliminates alignment problems, and contributes to the invention's elegantly simple design. Furthermore, there is no need for a separate "erase" signal as the write signal which energizes the coil is used.

This same concept may also be implemented in a ring head coil construction with a center pole comprising

0882278-032197

5

an I-pole piece having a coil wrapped therearound and two C-pole pieces surrounding the I-pole piece.

While the principal advantages and features of the present invention have been explained, a fuller understanding of the invention may be gained by referring to the drawings and description of the preferred embodiment.

#### Brief Description of the Drawings

Figure 1 is a schematic representation of a conventional inductive write head as known in the art, Figures 2(a) to (d) are perspectives detailing the construction of a thin film inductive head or write head manufactured through layering processes as known in the art,

Figures 3(a)-(d) are perspective views detailing the construction of the thin film inductive head of the present invention,

Figure 4 is a schematic representation of the prior art construction of a ring head coil detailing the use of two C pole pieces,

Figure 5 is a schematic representation of a prior art ring head coil utilizing a C and I pole piece, and

Figure 6 is a schematic representation of a ring head coil arrangement illustrating a write head with preconditioning gap of the present invention.

#### Description of the Preferred Embodiment

As shown in Fig. 1, it is well known in the prior art that a conventional inductive write head 20 is formed with a head core 22 made of magnetic material and formed in the general shape of a C with a gap 24 wherein a gap fringing field 26 is formed through energization of a coil 28 energized from a current source 30, all as is well known in the art. Also, a side fringing field 32 is formed along the side edges of gap 24. The magnetic flux in the gap fringing field 26 is emitted during writing, or erasing, as coil 28 is energized to magnetize a

5 pole tip width of each pole piece may be chosen to  
provide appropriately sized erase and write tracks,  
depending upon the particular application. One such  
configuration might include a preselected pole tip width  
for  $P_1$ , a wider pole tip width for  $P_2$ , and a pole tip  
width of  $P_3$  the same as that of  $P_1$ . This arrangement  
would provide a larger erase track width to overcome the  
potential problem of not completely erasing old  
information due to improper head alignment. Although, it  
10 would not be uncommon for the pole tip widths to be equal  
to provide erase and write track widths of comparable  
width. As is known in the art, the pole tips may be  
sized by planar lithography, pole tip trimming, or some  
other equivalent method.

15 In operation, a magnetic medium (not shown) would  
traverse the head construction of the present invention  
as depicted in Fig. 3(d) from right to left such that it  
would first be subjected to the magnetic field induced by  
preconditioning gap 110 to precondition it. As that  
20 portion of the magnetic medium passes under write gap  
116, its induced magnetization is known as it has been  
preconditioned or magnetically "written to" by  
preconditioning gap 110. Although, as mentioned above,  
the gap size for preconditioning gap 110 may be chosen as  
25 desired, it is presently thought that A-C erasure is more  
desired. Hence, a wider preconditioning gap 110 with a  
higher frequency data write signal will provide a  
decaying alternating field that will set the state of  
magnetization on the magnetic medium closer to that  
30 expected to be achieved with true A-C erasure. This is  
due in part to a wider gap not being as effective in  
creating a sharp transition. However, this is just one  
example of a particular construction which may be  
utilized, depending upon the particular application  
35 chosen.

9

There may also be manufacturing considerations which would impact on the choice of individual pole piece construction or gap sizing. For example, as depicted in Fig. 3(d) and explained herein, pole piece  $P_1$  (100) has been chosen to extend under the full width of coil 102, with pole piece  $P_2$  (104) attached near its center or medial portion, and pole piece  $P_3$  (106) attached near its end opposite the tip end. However, other alternative construction could be used and still satisfy the magnetic requirements of the head of the present invention. For example, pole piece  $P_2$  may be chosen to include the extension underlying the back half of coil 102. Or,  $P_3$  (106) may also be chosen to include that portion of a pole piece which underlies the back half of coil 102. Similarly, other configurations may be utilized to satisfy the coil requirements for the head of the present invention. For example, a separate or additional coil may be utilized which might, for example, surround pole piece  $P_3$  to provide a different preconditioning signal than the write signal.

As shown in Figure 4, the construction of a prior art ring head coil 140 may include a pair of C-shaped pole pieces 142, 144 joined by suitable means as known in the art at one end thereof, as shown at 146. One or more coils 148, 150 may be wrapped around the C-shaped pole pieces 142, 144 in order to energize a write or read gap 152 between the opposite ends 154, 156 of C-shaped pole pieces 142, 144. An alternative construction for a ring head coil 158 includes a C-shaped pole piece 160 and an I-shaped pole piece 162 joined at an end thereof as at 164 with a coil 166 wrapped around the I-shaped pole piece 162. In this construction, a read or write gap 168 is formed between the opposite ends 170, 172 of the two pole pieces 160, 162. This construction might be in some circumstances easier to manufacture as the coil 166 may be readily wrapped around the I-shaped pole piece 162

prior to its being joined as at joint 164 using convenient manufacturing methods, as known in the art.

The present invention may be implemented in the ring head coil 174 in a construction as depicted in Figure 6. In that construction, a center I-shaped pole piece 176 having a coil 178 wrapped therearound is surrounded on either side by a C-shaped pole piece 180, and a C-shaped pole piece 182, both of which are joined at an end to the I-shaped pole piece 166 at joints 184, 186. A write gap  $g_1$  is formed between the ends 188 of C-shaped pole piece 180 and end 190 of I-shaped pole piece 176. A preconditioning gap  $g_2$  is formed between the end 192 of C-shaped pole piece 182 and end 190 of I-shaped pole piece 176. In ring coils, write gaps may be somewhat larger than those in presently manufactured thin film heads. For example, write head gap  $g_1$  may be of a size of approximately .2 microns up to .5 microns, and even larger depending upon the particular application such as for video tape, etc. For purposes of the present invention, it is only important that the width of preconditioning gap  $g_2$  be chosen as is sufficient to precondition the magnetic medium prior to its being written on with write gap  $g_1$ . In the preferred embodiment, the inventor contemplates that the preconditioning gap  $g_2$  is larger than the write gap  $g_1$ .

Still another aspect of the present invention is the improvement in the head field gradient, and the ability of the manufacturer to alter and adjust the head field gradient by adjusting the gap widths. As shown by the inventors' prior work, the head field gradient may be sharpened to facilitate the writing of sharp transitions on a magnetic medium by locating a shim in an existing write gap. However, until the present invention, a physical embodiment or construction to implement a shim placement has not been known. With the present invention, an integral construction is provided which

08822778-032197

||

lends itself readily to location of the center pole piece and its use as part of both the write gap and preconditioning gap for achieving an improved or sharpened head field gradient. This sharpened head field gradient also renders the head more suitable for perpendicular recording for which sharp transitions are especially important.

Still other variations in construction may be considered and implemented by those skilled in the art in order to facilitate manufacture, or for other reasons, and yet not depart from the spirit and scope of the invention. The present invention shall not be considered to be limited to the construction of the preferred embodiment as has been previously described and instead should be limited only by the scope of the claims appended hereto, and their equivalents.
